Abstract

Infinite loops and redundant computations are long recognized open problems in Prolog. Two ways have been explored to resolve these problems: loop checking and tabling. Loop checking can cut infinite loops, but it cannot be both sound and complete even for function-free logic programs. Tabling seems to be an effective way to resolve infinite loops and redundant computations. However, existing tabulated resolutions, such as OLDT-resolution, SLG-resolution, and Tabulated SLS-resolution, are non-linear because they rely on the solution-lookup mode in formulating tabling. The principal disadvantage of non-linear resolutions is that they cannot be implemented using a simple stack-based memory structure like that in Prolog. Moreover, some strictly sequential operators such as cuts may not be handled as easily as in Prolog.

In this paper, we propose a hybrid method to resolve infinite loops and redundant computations. We combine the ideas of loop checking and tabling to establish a linear tabulated resolution called TP-resolution. TP-resolution has two distinctive features: (1) It makes linear tabulated derivations in the same way as Prolog except that infinite loops are broken and redundant computations are reduced. It handles cuts as effectively as Prolog. (2) It is sound and complete for positive logic programs with the bounded-term-size property. The underlying algorithm can be implemented by an extension to any existing Prolog abstract machines such as WAM or ATOAM.

Keywords: Tabling, loop checking, resolution, Prolog.

*Work performed during a visit at Department of Computing Science, University of Alberta, Canada.

1 Introduction

While Prolog has many distinct advantages, it suffers from some serious problems, among the best-known of which are infinite loops and redundant computations. Infinite loops cause users (especially less skilled users) to lose confidence in writing terminating Prolog programs, whereas redundant computations greatly reduce the efficiency of Prolog. The existing approaches to resolving these problems can be classified into two categories: loop checking and tabling.

Loop checking is a direct way to cut infinite loops. It locates nodes at which SLD-derivations step into a loop and prunes them from SLD-trees. Informally, an SLD-derivation $G_0 \Rightarrow_{C_1,\theta_1} G_1 \Rightarrow ... \Rightarrow_{C_i,\theta_i} G_i \Rightarrow ... \Rightarrow_{C_k,\theta_k} G_k \Rightarrow ...$ is said to step into a loop at a node N_k labeled with a goal G_k if there is a node N_i $(0 \leq i < k)$ labeled with a goal G_i in the derivation such that G_i and G_k are *sufficiently similar*. Many loop checking mechanisms have been presented in the literature (e.g. [2, 7, 8, 14, 16, 18, 20]). However, no loop checking mechanism can be both (weakly) sound and complete because the loop checking problem itself is undecidable in general even for function-free logic programs [2].

The main idea of tabling is that during top-down query evaluation, we store intermediate results of some subgoals and look them up to solve variants of the subgoals that occur later. Since no variant subgoals will be recomputed by applying the same set of program clauses, infinite loops can be avoided. As a result, termination can be guaranteed for bounded-term-size programs and redundant computations substantially reduced [4, 6, 17, 20, 22].

There are many ways to formulate tabling, each leading to a tabulated resolution (e.g. OLDT-resolution [17], SLG-resolution [6], Tabulated SLS-resolution [4], etc.). However, although existing tabulated resolutions differ in one aspect or another, all of them rely on the so called *solution-lookup mode*. That is, all nodes in a search tree/forest are partitioned into two subsets, *solution* nodes and *lookup* nodes; solution nodes produce child nodes using program clauses, whereas lookup nodes produce child nodes using answers in tables.

Our investigation shows that the principal disadvantage of the solution-lookup mode is that it makes tabulated resolutions non-linear. Let $G_0 \Rightarrow_{C_1,\theta_1} G_1 \Rightarrow ... \Rightarrow_{C_i,\theta_i} G_i$ be the current derivation with G_i being the latest generated goal. A tabulated resolution is said to be *linear*[1] if it makes the next derivation step either by expanding G_i by resolving a subgoal in G_i against a program clause or a tabled answer, which yields $G_i \Rightarrow_{C_{i+1},\theta_{i+1}} G_{i+1}$, or by expanding G_{i-1} via backtracking. It is due to such non-linearity that the underlying tabulated resolutions cannot be implemented in the same way as SLD-resolution (Prolog) using a simple stack-based memory structure. Moreover, some strictly sequential operators such as cuts (!) may not be handled as easily as in Prolog. For instance, in the well-known tabulated resolution system XSB, clauses like

$$p(.) \leftarrow ..., t(.), !, ...$$

[1] The concept of "linear" here is different from the one used for SL-resolution [9].

where $t(.)$ is a tabled subgoal, are not allowed because the tabled predicate t occurs in the scope of a cut [11, 13].

The objective of our research is to establish a hybrid approach to resolving infinite loops and redundant computations and develop a linear tabulated Prolog system. In this paper, we establish a theoretical framework for such a system, focusing on a linear tabulated resolution − *TP-resolution* for positive logic programs (TP for Tabulated Prolog).

Remark 1.1 In this paper we will use the prefix *TP* to name some key concepts such as TP-strategy, TP-tree, TP-derivation and TP-resolution, in contrast to the standard Prolog control strategy, Prolog-tree (i.e. SLD-tree generated under Prolog-strategy), Prolog-derivation and Prolog-resolution (i.e. SLD-resolution controlled by Prolog-strategy), respectively.

In TP-resolution, each node in a search tree can act not only as a solution node but also as a lookup node, regardless of when and where it is generated. In fact, we do not distinguish between solution and lookup nodes in TP-resolution. This shows an essential difference from existing tabulated resolutions using the solution-lookup mode. The main idea is as follows: for any selected tabled subgoal A at a node N_i labeled with a goal G_i, it always first uses an answer I in a table to generate a child node N_{i+1} (N_i acts as a lookup node), which is labeled by the resolvent of G_i and I; if no new answers are available in the table, it resolves against program clauses to produce child nodes (N_i then acts as a solution node). The order in which answers in a table are used is based on *first-generated-first-use* and the order in which program clauses are applied is from top to bottom except for the case where the derivation steps into a loop at N_i. In such a case, the subgoal A skips the clause that is being used by its closest ancestor subgoal that is a variant of A. Like OLDT-resolution, TP-resolution is sound and complete for positive logic programs with the bounded-term-size property.

The plan of this paper is as follows. In Section 2 we present a typical example to illustrate the main idea of TP-resolution and its key differences from existing tabulated resolutions. In Section 3, we formally define TP-resolution. In Section 3.1 we discuss how to represent tables and how to operate on tables. In Section 3.2 we first introduce the so called *PMF* mode for resolving tabled subgoals with program clauses, which lays the basis for a linear tabulated resolution. We then define a tabulated control strategy called *TP-strategy*, which enhances Prolog-strategy with proper policies for the selection of answers in tables. Next we present a constructive definition (an algorithm) of a *TP-tree* based on TP-strategy. Finally, based on TP-trees we define *TP-derivations* and *TP-resolution*.

Section 4 is devoted to showing some major characteristics of TP-resolution, including its termination property and soundness and completeness. We also discuss in detail how TP-resolution deals with the cut operator.

We assume familiarity with the basic concepts of logic programming, as presented in [10]. Here

and throughout, variables begin with a capital letter, and predicates, functions and constants with a lower case letter. By $\vec{E}$ we denote a list/tuple $(E_1, ..., E_m)$ of elements. Let $\vec{X} = (X_1, ..., X_m)$ be a list of variables and $\vec{I} = (I_1, ..., I_m)$ a list of terms. By $\vec{X}/\vec{I}$ we denote a substitution $\{X_1/I_1, ..., X_m/I_m\}$. By $p(.)$ we refer to any atom with the predicate p and by $p(\vec{X})$ to an atom $p(.)$ that contains the list $\vec{X}$ of distinct variables. For instance, if $p(\vec{X}) = p(W, a, f(Y), W)$, then $\vec{X} = (W, Y)$. Let $G =\leftarrow A_1, ..., A_m$ be a goal and B a subgoal. By $G + B$ we denote the goal $\leftarrow A_1, ..., A_m, B$. By a *variant* of an atom (resp. a subgoal or a term) A we mean an atom (resp. a subgoal or a term) A' that is the same as A up to variable renaming.[2] Let V be a set of atoms (resp. subgoals or terms) that are variants of each other; then they are called *variant atoms* (resp. *variant subgoals* or *variant terms*). Moreover, clauses with the same head predicate p are numbered sequentially, with C_{p_i} referring to its i-th clause ($i > 0$). Finally, unless otherwise stated, by a (logic) program we refer to a positive logic program with a finite set of clauses.

2 An Illustrative Example

We use the following simple program to illustrate the basic idea of the TP approach. For convenience of presentation, we choose OLDT-resolution [17] for a side-by-side comparison (other typical tabulated resolutions, such as SLG-resolution [6] and Tabulated SLS-resolution [4], have similar effects).

P_1: $reach(X, Y) \leftarrow reach(X, Z), edge(Z, Y).$ C_{r_1}
$reach(X, X).$ C_{r_2}
$reach(X, d).$ C_{r_3}

$edge(a, b).$ C_{e_1}
$edge(d, e).$ C_{e_2}

Let $G_0 =\leftarrow reach(a, X)$ be the query (top goal). Then Prolog will step into an infinite loop right after the application of the first clause C_{r_1}. We now show how it works using OLDT-resolution (under the depth-first control strategy). Starting from the root node N_0 labeled with the goal $\leftarrow reach(a, X)$, the application of the clause C_{r_1} gives a child node N_1 labeled with the goal $\leftarrow reach(a, Z), edge(Z, X)$ (see Figure 1). Since the subgoal $reach(a, Z)$ is a variant of $reach(a, X)$ that occurred earlier, it is suspended to wait for $reach(a, X)$ to produce answers. N_0 and N_1 (resp. $reach(a, X)$ and $reach(a, Z)$) are then called *solution* and *lookup* nodes (resp. subgoals), respectively. So the derivation goes back to N_0 and resolves $reach(a, X)$ with the second clause C_{r_2}, which gives a sibling node N_2 labeled with an empty clause $\square$. Since $reach(a, a)$ is an answer to the subgoal $reach(a, X)$, it is memorized in a table, say $TB(reach(a, X))$. The derivation then jumps back to N_1 and uses the answer $reach(a, a)$ in the table to resolve with the lookup subgoal

[2] By this definition, A is a variant of itself.

$reach(a, Z)$, which gives a new node N_3 labeled with $\leftarrow edge(a, X)$. Next, the node N_4 labeled with $\square$ is derived from N_3 by resolving the subgoal $edge(a, X)$ with the clause C_{e_1}. So the answer $reach(a, b)$ is added to the table $TB(reach(a, X))$. After these steps, the OLDT-derivation evolves into a tree as depicted in Figure 1, which is clearly not linear.

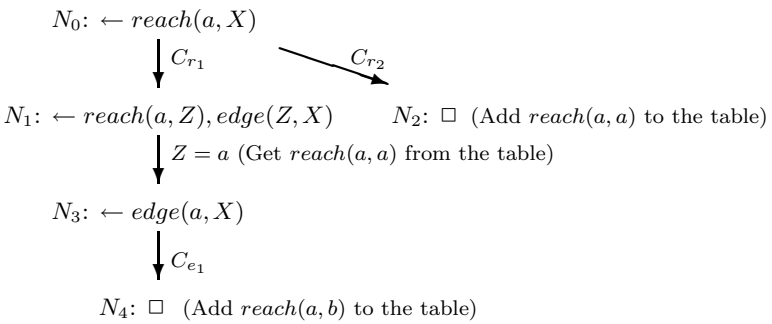

Figure 1: OLDT-derivation.

We now explain how TP-resolution works. Starting from the root node N_0 labeled with the goal $\leftarrow reach(a, X)$ we apply the clause C_{r_1} to derive a child node N_1 labeled with the goal $\leftarrow reach(a, Z), edge(Z, X)$ (see Figure 2). As the subgoal $reach(a, Z)$ is a variant of $reach(a, X)$ and the latter is an *ancestor* of the former (i.e., the derivation steps into a loop at N_1 [14]), we choose C_{r_2}, the clause from the backtracking point of the subgoal $reach(a, X)$, to resolve with $reach(a, Z)$, which gives a child node N_2 labeled with $\leftarrow edge(a, X)$. Since $reach(a, a)$ is an answer to the subgoal $reach(a, Z)$, it is memorized in a table $TB(reach(a, X))$. We then resolve the subgoal $edge(a, X)$ against the clause C_{e_1}, which gives the leaf N_3 labeled with $\square$. So the answer $reach(a, b)$ to the subgoal $reach(a, X)$ is added to the table $TB(reach(a, X))$. After these steps, we get a path as shown in Figure 2, which is clearly linear.

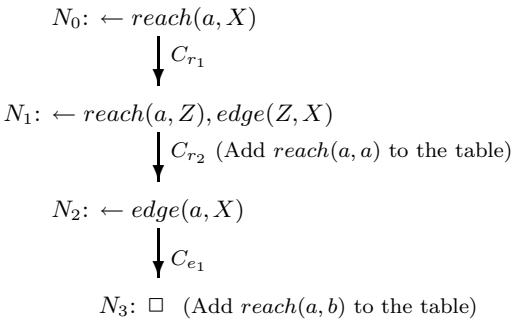

Figure 2: TP-derivation.

Now consider backtracking. Remember that after the above derivation steps, the table $TB($ $reach(a, X))$ consists of two answers, $reach(a, a)$ and $reach(a, b)$. For the OLDT approach, it first backtracks to N_3 and then to N_1 (Figure 1). Since the subgoal $reach(a, Z)$ has used the first answer in the table before, it resolves with the second, $reach(a, b)$, which gives a new node labeled with the goal $\leftarrow edge(b, X)$. Obviously, this goal will fail, so it backtracks to N_1 again. This time no new

answers in the table are available to the subgoal $reach(a, Z)$, so it is suspended and the derivation goes to the solution node N_0. The third clause C_{r_3} is then selected to resolve with the subgoal $reach(a, X)$, yielding a new answer $reach(a, d)$, which is added to the table. The derivation then goes back to N_1 where the new answer is used in the same way as described before.

The TP approach does backtracking in the same way as the OLDT approach except for the following key differences: (1) Because we do not distinguish between solution and lookup nodes/subgoals, when no new answers in the table are available to the subgoal $reach(a, Z)$ at N_1, we backtrack the subgoal by resolving it against the next clause C_{r_3}. This guarantees that TP-derivations are always linear. (2) Since there is a loop between N_0 and N_1, before failing the subgoal $reach(a, X)$ at N_0 via backtracking we need to be sure that the subgoal has got its complete set of answers. This is achieved by performing *answer iteration* via the loop. That is, we regenerate the loop to see if any new answers can be derived until we reach a fixpoint. Figure 3 shows the first part of TP-resolution, where the following answers to G_0 are derived: $X = a$, $X = b$, $X = d$ and $X = e$. Figure 4 shows the part of answer iteration. Since no new answer is derived during the iteration (i.e. no answer is added to any tables), we fail the subgoal $reach(a, X)$ at N_0.

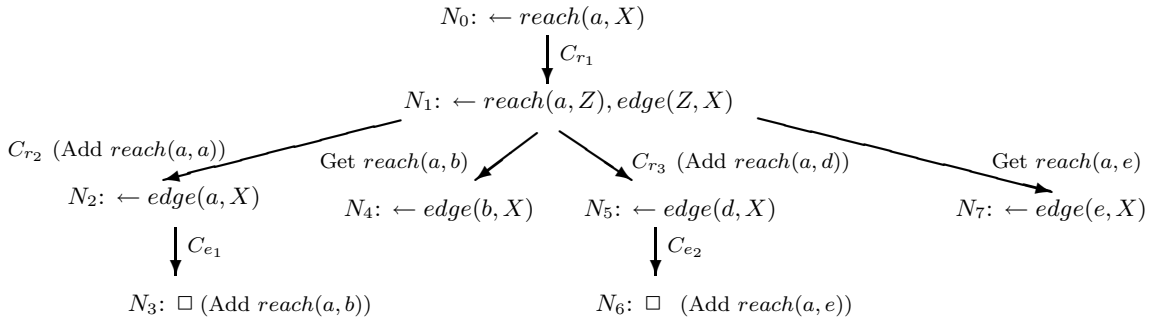

Figure 3: TP-derivations of $P_1 \cup \{G_0\}$.

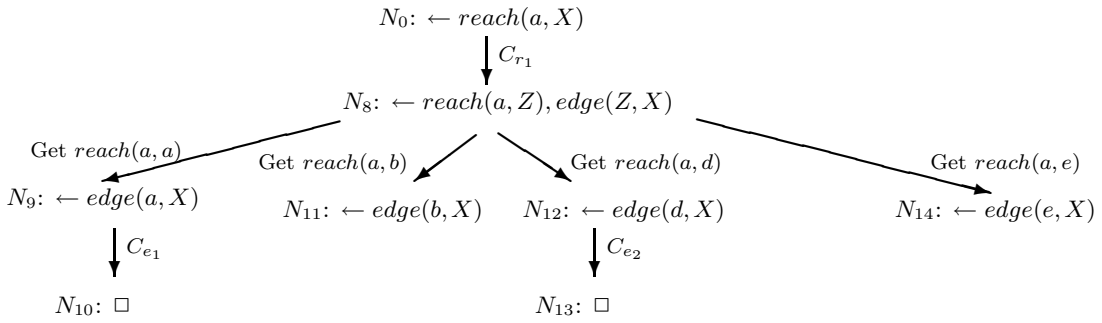

Figure 4: Answer iteration via a loop.

Remark 2.1 From the above illustration, we see that in OLDT-resolution, solution nodes are those at which the left-most subgoals are generated earliest among all their variant subgoals. In SLG-resolution, however, solution nodes are roots of trees in a search forest, each labeled by a special clause of the form $A \leftarrow A$ [5]. In Tabulated SLS-resolution, any root of a tree in a forest is

itself labeled by an instance, say $A \leftarrow B_1, ..., B_n$ $(n \geq 0)$, of a program clause and no nodes in the tree will produce child nodes using program clauses [3]. However, for any atom A we can assume a virtual super-root labeled with $A \leftarrow A$, which takes all the roots in the forest labeled by $A \leftarrow ...$ as its child nodes. In this sense, the search forest in Tabulated SLS-resolution is the same as that in SLG-resolution for positive logic programs. Therefore, we can consider all virtual super-roots as solution nodes.

3 TP-Resolution

This section formally defines the TP approach to tabulated resolution, mainly including the representation of tables, the strategy for controlling tabulated derivations (TP-strategy), and the algorithm for making tabulated derivations based on the control strategy (TP-trees).

3.1 Tabled Predicates and Tables

Predicates in a program P are classified as *tabled predicates* and *non-tabled predicates*. The classification is made based on a *dependency graph* [1]. Informally, for any predicates p and q, there is an edge $p \rightarrow q$ in a dependency graph G_P if there is a clause in P of the form $p(.) \leftarrow ..., q(.), ...$ Then a predicate p is to be tabled if G_P contains a cycle with a node p.

Any atom/subgoal with a tabled predicate is called a *tabled atom/subgoal*. During tabulated resolution, we will create a table for each tabled subgoal, A. Apparently, the table must contain A (as an index) and have space to store intermediate answers of A. Note that in our tabling approach, any tabled subgoal can act both as a solution subgoal and as a lookup subgoal, so a table can be viewed as a blackboard on which a set of variant subgoals will read and write answers. In order to guarantee not losing answers for any tabled subgoals (i.e. the table should contain all answers that A is supposed to have by applying its related clauses), while avoiding redundant computations (i.e. after a clause has been used by A, it should not be re-used by any other variant subgoal A'), a third component is needed in the table that keeps the status of the clauses related to A. Therefore, after a clause C_i has been used by A, we change its status. Then when evaluating a new subgoal A' that is a variant of A, C_i will be ignored because all answers of A derived via C_i have already been stored in the table. For any clause whose head is a tabled atom, its status can be *"no longer available"* or *"still available."* We say that C_i is *"no longer available"* to A if all answers of A through the application of C_i have already been stored in the table of A. Otherwise, we say C_i is *"still available"* to A. Finally, we need a flag variable $COMP$ in the table to indicate if all answers through the application of all clauses related to A have been completely stored in the table. This leads to the following.

Definition 3.1 Let P be a logic program and $p(\vec{X})$ a tabled subgoal. Let P contain exactly

M clauses, $C_{p_1}, ..., C_{p_M}$, with a head $p(.)$. A *table* for $p(\vec{X})$, denoted $TB(p(\vec{X}))$, is a four-tuple $(p(\vec{X}), T, C, COMP)$, where

1. T consists of tuples that are instances of $\vec{X}$, each $\vec{I}$ of which represents an answer, $p(\vec{X})\vec{X}/\vec{I}$, to the subgoal.
2. C is a vector of M elements, with $C[i] = 0$ (resp. $= 1$) representing that the status of C_{p_i} w.r.t. $p(\vec{X})$ is *"no longer available"* (resp. *"still available"*).
3. $COMP \in \{0, 1\}$, with $COMP = 1$ indicating that the answers of $p(\vec{X})$ have been completed.

For convenience, we use $TB(p(\vec{X})) \rightarrow answer_tuple[i]$ to refer to the i-th answer tuple in T, $TB(p(\vec{X})) \rightarrow clause_status[i]$ to the status of C_{p_i} w.r.t. $p(\vec{X})$, and $TB(p(\vec{X})) \rightarrow COMP$ to the flag $COMP$.

Example 3.1 Let P be a logic program that contains exactly three clauses, C_{p_1}, C_{p_2} and C_{p_3}, with a head $p(.)$. The table

$$TB(p(X,Y)) : (p(X,Y),\ \{(a,b),(b,a),(b,c)\},(1,0,0),0)$$

represents that there are three answers to $p(X,Y)$, namely $p(a,b)$, $p(b,a)$ and $p(b,c)$, and that C_{p_2} and C_{p_3} have already been used by $p(X,Y)$ (or its variant subgoals) and C_{p_1} is still available to $p(X,Y)$. Obviously, the answers of $p(X,Y)$ have not yet been completed. The table

$$TB(p(a,b)) : (p(a,b),\ \{()\},(0,1,1),1)$$

shows that $p(a,b)$ has been proved true after applying C_{p_1}. Note that since $p(a,b)$ contains no variables, its answer is a 0-ary tuple. Finally, the table

$$TB(p(a,X)) : (p(a,X),\ \{\},(0,0,0),1)$$

represents that $p(a,X)$ has no answer at all.

Before introducing operations on tables, we define the structure of nodes used in TP-resolution.

Definition 3.2 Let P be a logic program and G_i a goal $\leftarrow p(\vec{X}), A_2, ..., A_m$. By *"register a node N_i with G_i"* we do the following: (1) label N_i with G_i, i.e. $N_i :\leftarrow p(\vec{X}), A_2, ..., A_m$; and (2) create the following structure for N_i:

- $answer_ptr$, a pointer that points to an answer tuple in $TB(p(\vec{X}))$.
- $clause_ptr$, a pointer that points to a clause in P with a head $p(.)$.
- $clause_SUSP$ (initially =0), a flag used for the update of clause status.
- $node_LOOP$ (initially =0), a flag showing if N_i is a loop node.
- $node_ITER$ (initially =0), a flag showing if N_i is an iteration node.
- $node_ANC$ (initially $=-1$), a flag showing if N_i has any ancestor variant subgoals.

For any field F in the structure of N_i, we refer to it by $N_i \rightarrow F$. The meaning of $N_i \rightarrow answer_ptr$ and $N_i \rightarrow clause_ptr$ is obvious. The remaining fields will be defined by Definition 3.8 followed by the procedure *nodetype_update*(.). We are now ready to define operations on tables.

Definition 3.3 Let P be a logic program with M clauses with a head $p(.)$ and N_i a node labeled by a goal $\leftarrow p(\vec{X}), ..., A_m$. Let NEW be a global flag variable used for answer iteration (see Algorithm 2 for details). We have the following basic operations on a table.

1. $create(p(\vec{X}))$. Create a table $TB(p(\vec{X})) : (p(\vec{X}), T, C, COMP)$, with $T = \{\}$, $COMP = 0$, and $C[j] = 1$ for all $1 \leq j \leq M$.
2. $memo(p(\vec{X}), \vec{I})$, where $\vec{I}$ is an instance of $\vec{X}$. When $\vec{I}$ is not in $TB(p(\vec{X}))$, add it to the end of the table, set $NEW = 1$, and if $\vec{I}$ is a variant of $\vec{X}$, set $TB(p(\vec{X})) \rightarrow COMP = 1$.
3. $lookup(N_i, \vec{I}_i)$. Fetch the next answer tuple in $TB(p(\vec{X}))$, which is pointed by $N_i \rightarrow answer_ptr$, into $\vec{I}_i$. If there is no next tuple, $\vec{I}_i = null$.
4. $memo_look(N_i, p(\vec{X}), \vec{I}, \theta_i)$. It is a compact operator, which combines $memo(.)$ and $lookup(.)$. That is, it first performs $memo(p(\vec{X}), \vec{I})$ and then gets the next answer tuple $\vec{F}$ from $TB(p(\vec{X}))$, which together with $\vec{X}$ forms a substitution $\theta_i = \vec{X}/\vec{F}$. If there is no next tuple, $\theta_i = null$.

First, the procedure $create(p(\vec{X}))$ is called only when the subgoal $p(\vec{X})$ occurs the first time and no variant subgoals occurred before. Therefore, up to the time when we call $create(p(\vec{X}))$, no clauses with a head $p(.)$ in P have been selected by any variant subgoals of $p(\vec{X})$, so their status should be set to 1. Second, whenever an answer $p(\vec{I})$ of $p(\vec{X})$ is derived, we call the procedure $memo(p(\vec{X}), \vec{I})$. If the answer is new, it is appended to the end of the table. The flag NEW is then set to 1, showing that a new answer has been derived. If the new tuple $\vec{I}$ is a variant of $\vec{X}$, which means that $p(\vec{X})$ is true for any instances of $\vec{X}$, the answers of $p(\vec{X})$ are completed so $TB(p(\vec{X})) \rightarrow COMP$ is set to 1. Finally, $lookup(N_i, \vec{I}_i)$ is used to fetch an answer tuple from the table for the subgoal $p(\vec{X})$ at N_i.

$memo(.)$ and $lookup(.)$ can be used independently. They can also be used in pairs, i.e. $memo(.)$ immediately followed by $lookup(.)$. In the latter case, it would be more convenient to use $memo_look(.)$.

3.2 TP-Strategy and TP-Trees

In this subsection, we introduce the tabulated control strategy and the way to make tabulated derivations based on this strategy. We begin by discussing how to resolve subgoals with program clauses and answers in tables.

Let N_i be a node labeled by a goal $G_i = \leftarrow A_1, ..., A_m$ with $A_1 = p(\vec{X})$ a tabled subgoal. Consider evaluating A_1 using a program clause $C_p = A \leftarrow B_1, ..., B_n$ $(n \geq 0)$, where $A_1\theta =$

$A\theta$.[3] If we use SLD-resolution, we would obtain a new node labeled with the goal $G_{i+1} = \leftarrow (B_1, ..., B_n, A_2, ..., A_m)\theta$, where the mgu θ is *consumed* by all A_js ($j > 1$), although the proof of $A_1\theta$ has not yet been completed (*produced*). In order to avoid such kind of pre-consumption, we propose the so called *PMF* (for Prove-Memorize-Fetch) mode for resolving tabled subgoals with clauses. That is, we first prove $(B_1, ..., B_n)\theta$. If it is true with an mgu θ_1, which means $A_1\theta\theta_1$ is true, we memorize the answer $A_1\theta\theta_1$ in the table $TB(A_1)$ if it is new. We then fetch an answer from $TB(A_1)$ to apply to the remaining subgoals of G_i. Obviously modifying SLD-resolution by the PMF mode preserves the original answers to G_i. Moreover, since only new answers are added to $TB(A_1)$, all repeated answers of A_1 will be precluded to apply to the remaining subgoals of G_i, so that redundant computations are avoided.

The PMF mode can readily be realized by using the two table procedures, *memo*(.) and *lookup*(.), or using the compact operator *memo_look*(.). That is, after resolving the subgoal A_1 with the clause C_p, N_i gets a child node N_{i+1} labeled with the goal

$$G_{i+1} = \leftarrow (B_1, ..., B_n)\theta, memo_look(N_i, p(\vec{X}), \vec{X}\theta, \theta_i), A_2, ..., A_m.$$

Note that the application of θ is blocked by the subgoal *memo_look*(.) because the consumption (fetch) must follow the production (prove and memorize). We now explain how it works.

Assume that after some resolution steps from N_{i+1} we reach a node N_k that is labeled by the goal $G_k = \leftarrow memo_look(N_i, p(\vec{X}), \vec{X}\theta\theta_1, \theta_i), A_2, ..., A_m$. This means that $(B_1, ..., B_n)\theta$ has been proved true with the mgu θ_1. That is, $A_1\theta\theta_1$ is an answer of A_1. By the left-most computation rule, $memo_look(N_i, p(\vec{X}), \vec{X}\theta\theta_1, \theta_i)$ is executed, which adds to the table $TB(A_1)$ the answer tuple $\vec{X}\theta\theta_1$ if it is new, gets from $TB(A_1)$ the next tuple $\vec{I}$, and then sets $\theta_i = \vec{X}/\vec{I}$. Since $A_1\theta_i$ is an answer to the subgoal A_1 of G_i, the mgu θ_i needs to be applied to the remaining A_js of G_i. We distinguish between two cases.

(1) From A_2 to A_m, $A_j = memo_look(N_f, B, _, \theta_f)$ is the first subgoal of the form *memo_look*(.). According to the PMF mode, there must be a node N_f, which occurred earlier than N_i, labeled with a goal $G_f = \leftarrow B, A_{j+1}, ..., A_m$ such that B is a tabled subgoal and $A_j = memo_look(N_f, B, _, \theta_f)$ resulted from resolving B with a program clause. This means that the proof of B is now reduced to the proof of $(A_2, ..., A_{j-1})\theta_i$. Therefore, by the PMF mode θ_i should be applied to the subgoals A_2 until A_j. That is, N_k has a child node N_{k+1} labeled with a goal $G_{k+1} = \leftarrow (A_2, ..., A_j)\theta_i, A_{j+1}, ..., A_m$.

(2) For no $j \geq 2$ A_j is of the form *memo_look*(.). This means that no A_j is a descendant of any tabled subgoal, so the mgu θ_i should be applied to all the A_js. That is, $G_{k+1} = \leftarrow (A_2, ..., A_m)\theta_i$.

Note that by Definition 3.3 the atom $p(\vec{X})$ in $memo(p(\vec{X}), _)$ and $memo_look(_, p(\vec{X}), _, _)$ is merely used to index the table $TB(p(\vec{X}))$, so it cannot be instantiated during the resolution.

[3]Here and throughout, we assume that C_p has been standardized apart to share no variables with G_i.

That is, for any mgu θ, $memo(p(\vec{X}), \vec{I})\theta = memo(p(\vec{X}), \vec{I}\theta)$ and $memo_look(N_i, p(\vec{X}), \vec{I}, \theta_i)\theta = memo_look(N_i, p(\vec{X}), \vec{I}\theta, \theta_i)$

The above discussion shows how to resolve the tabled subgoal A_1 at N_i against a program clause using the PMF mode. The same principle can be applied to resolve A_1 with an answer tuple $\vec{I}$ in $TB(A_1)$ and to resolve A_1 with a program clause when A_1 is a non-tabled subgoal. Therefore, we have the following definition of resolvents for TP-resolution.

Definition 3.4 Let N_i be a node labeled by a goal $G_i = \leftarrow A_1, ..., A_m$ $(m \geq 1)$.

1. If A_1 is $memo_look(N_h, p(\vec{X}), \vec{I}, \theta_h)$, then the *resolvent* of G_i and θ_h $(\theta_h \neq null)$ is the goal $G_{i+1} = \leftarrow (A_2, ..., A_k)\theta_h, A_{k+1}, ..., A_m$, where A_k $(k > 1)$ is the left-most subgoal of the form $memo_look(.)$.

   Otherwise, let $A_1 = p(\vec{X})$ and C_p be a program clause $A \leftarrow B_1, ..., B_n$ with $A\theta = A_1\theta$.

2. If A_1 is a non-tabled subgoal, the *resolvent* of G_i and C_p is the goal $G_{i+1} = \leftarrow (B_1, ..., B_n, A_2, ..., A_k)\theta$, $A_{k+1}, ..., A_m$, where A_k is the left-most subgoal of the form $memo_look(.)$.

3. If A_1 is a tabled subgoal, the *resolvent* of G_i and C_p is the goal $G_{i+1} = \leftarrow (B_1, ..., B_n)\theta$, $memo_look(N_i, p(\vec{X}), \vec{X}\theta, \theta_i), A_2, ..., A_m$.

4. If A_1 is a tabled subgoal, let $\vec{I}$ $(\vec{I} \neq null)$ be an answer tuple in $TB(A_1)$, then the *resolvent* of G_i and $\vec{I}$ is the goal $G_{i+1} = \leftarrow (A_2, ..., A_k)\vec{X}/\vec{I}, A_{k+1}, ..., A_m$, where A_k is the left-most subgoal of the form $memo_look(.)$.

We now discuss tabulated control strategies. Recall that Prolog implements SLD-resolution by sequentially searching an SLD-tree using the Prolog control strategy (*Prolog-strategy*, for short): **Depth-first** (for goal selection) + **Left-most** (for subgoal selection) + **Top-down** (for clause selection) + **Last-first** (for backtracking). Let *"register a node N_i with G_i"* be as defined by Definition 3.2 except that the structure of N_i only contains the pointer *clause_ptr*. Let $return(\vec{Z})$ be a procedure that returns $\vec{Z}$ when $\vec{Z} \neq ()$ and *YES* otherwise. Then the way that Prolog makes SLD-derivations based on Prolog-strategy can be formulated as follows.

Definition 3.5 (Algorithm 1) Let P be a logic program and G_0 a top goal with the list $\vec{Y}$ of variables. The *Prolog-tree* T_{G_0} of $P \cup \{G_0\}$ is constructed by recursively performing the following steps until the answer NO is returned.

1. (Root node) Register the root N_0 with $G_0 + return(\vec{Y})$ and goto 2.

2. (Node expansion) Let N_i be the latest registered node labeled by $G_i = \leftarrow A_1, ..., A_m$ $(i \geq 0, m > 0)$. Register N_{i+1} as a child of N_i with G_{i+1} if G_{i+1} can be obtained as follows.

- Case 1: A_1 is $return(.)$. Execute the procedure $return(.)$, set $G_{i+1} = \Box$ (an empty clause), and goto 3 with $N = N_i$.
- Case 2: A_1 is an atom. Get a program clause $A \leftarrow B_1, ..., B_n$ (top-down via the pointer $N_i \rightarrow clause_ptr$) such that $A_1\theta = A\theta$. If no such a clause exists, then goto 3 with $N = N_i$; else set $G_{i+1} = \leftarrow (B_1, ...B_n, A_2, ..., A_m)\theta$ and goto 2.

3. (Backtracking) If N is the root, then return NO; else goto 2 with its parent node as the latest registered node.

Let ST_{G_0} be the SLD-tree of $P \cup \{G_0\}$ via the left-most computation rule.[4] It is easy to prove that when P has the bounded-term-size property [19] and ST_{G_0} contains no infinite loops, Algorithm 1 is sound and complete in that $T_{G_0} = ST_{G_0}$. Moreover, Algorithm 1 has the following distinct advantages: (1) since SLD-resolution is linear, Algorithm 1 can be efficiently implemented using a simple stack-based memory structure; (2) due to its linearity and regular sequentiality, some useful control mechanisms, such as the well-known cut operator !, can be used to heuristically reduce search space. Unfortunately, Algorithm 1 suffers from two serious problems. One is that it is easy to get into infinite loops even for very simple programs such as $P = \{p(X) \leftarrow p(X)\}$, which makes it incomplete in many cases. The second problem is that it unnecessarily re-applies the same set of clauses to variant subgoals such as in the query $\leftarrow p(X), p(Y)$, which leads to unacceptable performance.

As tabling has a distinct advantage of resolving infinite loops and redundant derivations, one interesting question then arises: Can we enhance Algorithm 1 with tabling, making it free from infinite loops and redundant computations while preserving the above two advantages? In the rest of this subsection, we give a constructive answer to this question. We first discuss how to enhance Prolog-strategy with tabling.

Observe that in a tabling system, we will have both program clauses and tables. For convenience, we refer to answer tuples in tables as *tabled facts*. Therefore, in addition to the existing policies in Prolog-strategy, we need to have the following two additional policies: (1) when both program clauses and tabled facts are available, first use tabled facts (i.e. **Table-first** for program and table selection); (2) when there are more than one tabled fact available, first use the one that is earliest memorized. Since we always add new answers to the end of tables (see Definition 3.3 for $memo(.)$), policy (2) amounts to saying **Top-down** selection for tabled facts. This leads to the following control strategy for tabulated derivations.

Definition 3.6 By *TP-strategy* we mean: Depth-first (for goal selection) + Left-most (for subgoal selection) + Table-first (for program and table selection) + Top-down (for the selection of tabled facts and program clauses) + Last-first (for backtracking).

[4] In [17], it is called an *OLD-tree*.

Our goal is to extend Algorithm 1 to make linear tabulated derivations based on TP-strategy. To this end, we need to review a few concepts concerning loop checking.

Definition 3.7 ([14] with slight modification) An *ancestor list* AL_A of pairs (N, B) is associated with each tabled subgoal A at a node N_i in a tree (see the TP-tree below), which is defined recursively as follows.

1. If A is at the root, then $AL_A = \{\}$.
2. If A inherits a subgoal A' (by copying or instantiation) from its parent node, then $AL_A = AL_{A'}$.
3. Let A be in the resolvent of a subgoal B at N_f against a clause $B' \leftarrow A_1, ..., A_n$ with $B\theta = B'\theta$ (i.e. $A = A_i\theta$ for some $1 \leq i \leq n$). If B is a tabled subgoal, $AL_A = AL_B \cup \{(N_f, B)\}$; otherwise $AL_A = \{\}$.

We see that for any tabled subgoals A and A', if A is in the ancestor list of A', i.e. $(_, A) \in AL_{A'}$, the proof of A needs the proof of A'. Particularly, if $(_, A) \in AL_{A'}$ and A' is a variant of A, the derivation goes into a loop. This leads to the following.

Definition 3.8 Let G_i at N_i and G_k at N_k be two goals in a derivation and A_i and A_k be the left-most subgoals of G_i and G_k, respectively. We say A_i (resp. N_i) is an *ancestor subgoal* of A_k (resp. an *ancestor node* of N_k) if $(N_i, A_i) \in AL_{A_k}$. If A_i is both an ancestor subgoal and a variant, i.e. an *ancestor variant subgoal*, of A_k, we say the derivation goes into a *loop*, denoted $L(N_i, N_k)$. Then, N_k and all its ancestor nodes involved in the loop are called *loop nodes*. N_i is also called the *top loop node* of the loop. Finally, a loop node is called an *iteration node* if by the time the node is about to fail through backtracking, it is the top loop node of all loops containing the node that were generated before.

Example 3.2 Figure 5 shows four loops, L_1, ..., L_4, with N_1, ..., N_4 their respective top loop nodes. We see that only N_1 and N_4 are iteration nodes.

Information about the types and ancestors of nodes is the basis on which we make tabulated resolution. Such information is kept in the structure of each node N_i (see Definition 3.2). The flag $N_i \rightarrow node_LOOP = 1$ shows that N_i is a loop node. The flag $N_i \rightarrow node_ITER = 1$ shows that N_i is an (candidate) iteration node. Let $A_1 = p(\vec{X})$ be the left-most subgoal at N_i. The flag $N_i \rightarrow node_ANC = -1$ represents that it is unknown whether A_1 has any ancestor variant subgoal; $N_i \rightarrow node_ANC = 0$ shows that A_1 has no ancestor variant subgoal; and $N_i \rightarrow node_ANC = j$ $(j > 0)$ indicates that A_1 has ancestor variant subgoals and that C_{p_j} is the clause that is being used

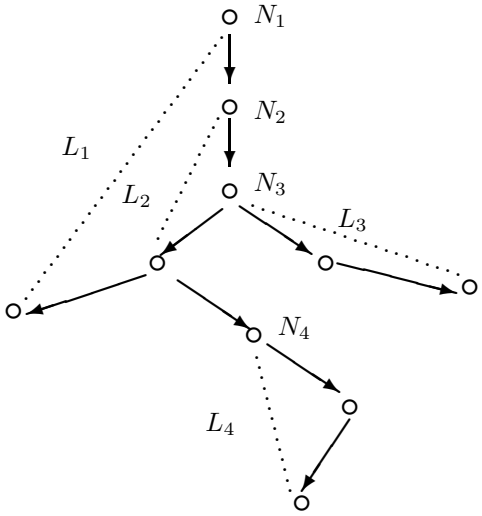

Figure 5: Loops, top loop nodes and iteration nodes.

by its closest ancestor variant subgoal (i.e., let A_h at N_h be the closest ancestor variant subgoal of A_1, then $N_i \rightarrow node_ANC = j$ represents that N_i is derived from N_h via C_{p_j}).

Once a loop, say $L(N_1, N_m)$, of the form

$$(N_1 :\leftarrow A_1, ...) \rightarrow_{C_{p_j},\theta_1} (N_2 :\leftarrow A_2, ...) \rightarrow ... \rightarrow (N_m :\leftarrow A_m, ...)$$

occurs, where all N_is ($i < m$) are ancestor nodes of N_m and $A_1 = p(\vec{X})$ is the closest ancestor variant subgoal of A_m, we update the flags of all nodes, $N_1, ..., N_m$, involved in the loop by calling the following procedure.

Procedure *nodetype_update*$(L(N_1, N_m))$

(1) For all $i > 1$ set $N_i \rightarrow node_LOOP = 1$ and $N_i \rightarrow node_ITER = 0$.

(2) If $N_1 \rightarrow node_LOOP = 0$, set $N_1 \rightarrow node_LOOP = 1$ and $N_1 \rightarrow node_ITER = 1$.

(3) Set $N_m \rightarrow node_ANC = j$.

(4) For all $i < m$ set $N_i \rightarrow clause_SUSP = 1$.

Point (1) is straightforward, where since N_1 is the top loop node of $L(N_1, N_m)$, all the remaining nodes in the loop cannot be an iteration node (see Definition 3.8).

If $N_1 \rightarrow node_LOOP = 0$, meaning that N_1 is not involved in any loop that occurred before, N_1 is considered as a *candidate* iteration node (point (2)). A candidate iteration node becomes an iteration node if the node keeps its candidacy by the time it is about to fail through backtracking (by that time it must be the top loop node of all previously generated loops containing it).

Since A_1 is the closest ancestor variant subgoal of A_m and C_{p_j} is the clause that is being used by A_1, we set the flag $N_m \rightarrow node_ANC = j$ (point (3)).

As mentioned in Section 2, during TP-resolution when a loop $L(N_1, N_m)$ occurs, where the left-most subgoal $A_1 = p(\vec{X})$ at N_1 is the closest ancestor variant subgoal of the left-most subgoal

A_m at N_m, A_m will skip the clause C_{p_j} that is being used by A_1. In order to ensure that such a skip will not lead to loss of answers to A_1, we will do answer iteration before failing N_1 via backtracking until we reach a fixpoint of answers. Answer iteration is done by regenerating $L(N_1, N_m)$. This requires keeping the status of all clauses being used by the loop nodes to *"still available"* during backtracking. Point (4) is used for such a purpose. After the flag $N_i \rightarrow clause_SUSP$ is set to 1, which indicates that N_i is currently involved in a loop, the status of the clause being currently used by N_i will not be set to *"no longer available"* when backtracking on N_i (see Case B3 of Algorithm 2).

Remark 3.1 We do answer iteration only at iteration nodes because they are the top nodes of all loops involving them. If we did answer iteration at a non-iteration loop node N, we would have to do it again at some top loop node N_{top} of N, in order to reach a fixpoint at N_{top} (see Figure 5). This would certainly lead to more redundant computations.

We are now in a position to define the TP-tree, which is constructed based on the TP-strategy using the following algorithm.

Definition 3.9 (Algorithm 2) Let P be a logic program and G_0 a top goal with the list $\vec{Y}$ of variables. The *TP-tree* TP_{G_0} of $P \cup \{G_0\}$ is constructed by recursively performing the following steps until the answer NO is returned.

1. (Root node) Register the root N_0 with $G_0 + return(\vec{Y})$, set $NEW = 0$, and goto 2.

2. (Node expansion) Let N_i be the latest registered node labeled by $G_i = \leftarrow A_1, ..., A_m$ $(m > 0)$. Register N_{i+1} as a child of N_i with G_{i+1} if G_{i+1} can be obtained as follows.

   - Case 1: A_1 is $return(.)$. Execute the procedure $return(.)$, set $G_{i+1} = \square$ (an empty clause), and goto 3 with $N = N_i$.
   - Case 2: A_1 is $memo_look(N_h, p(\vec{X}), \vec{I}, \theta_h)$. Execute the procedure.[5] If $\theta_h = null$ then goto 3 with $N = N_i$; else set G_{i+1} to the resolvent of G_i and θ_h and goto 2.
   - Case 3: A_1 is a non-tabled subgoal. Get a clause C whose head is unifiable with A_1.[6] If no such a clause exists then goto 3 with $N = N_i$; else set G_{i+1} to the resolvent of G_i and C and goto 2.
   - Case 4: $A_1 = p(\vec{X})$ is a tabled subgoal. Get an instance $\vec{I}$ of $\vec{X}$ from the table $TB(A_1)$. If $\vec{I} \neq null$ then set G_{i+1} to the resolvent of G_i and $\vec{I}$ and goto 2. Otherwise, if $TB(A_1) \rightarrow COMP = 1$ then goto 3 with $N = N_i$; else

[5] See Definition 3.3, where the flags NEW and $TB(p(\vec{X})) \rightarrow COMP$ will be updated.

[6] Here and throughout, clauses and answers in tables are selected top-down via the pointers $N_i \rightarrow clause_ptr$ and $N_i \rightarrow answer_ptr$, respectively.

- Case 4.1: $N_i \rightarrow node_ANC = -1$. If A_1 has no ancestor variant subgoal, set $N_i \rightarrow node_ANC = 0$ and goto Case 4.2. Otherwise, let N_h be the closest ancestor node of N_i such that $L(N_h, N_i)$ is a loop. Call $nodetype_update(L(N_h, N_i))$ and goto Case 4.3.
- Case 4.2: $N_i \rightarrow node_ANC = 0$. Get a clause C_{p_j} whose head is unifiable with A_1 such that $TB(A_1) \rightarrow clause_status[j] = 1$. If such a clause exists, set G_{i+1} to the resolvent of G_i and C_{p_j} and goto 2. Otherwise, if $N_i \rightarrow node_ITER = 0$ then goto 3 with $N = N_i$; else
  * Case 4.2.1: $NEW = 0$. Set $TB(A_1) \rightarrow COMP = 1$ and goto 3 with $N = N_i$.
  * Case 4.2.2: $NEW = 1$. Set $NEW = 0$, reset $N_i \rightarrow clause_ptr$ to pointing to the first clause C_{p_j} whose status is *"still available"*, and goto Case 4.2.
- Case 4.3: $N_i \rightarrow node_ANC = j$ $(j > 0)$. Get a clause C_{p_k} $(k > j)$ whose head is unifiable with A_1 such that $TB(A_1) \rightarrow clause_status[k] = 1$. If such a clause exists then set G_{i+1} to the resolvent of G_i and C_{p_k} and goto 2; else goto 3 with $N = N_i$.

3. (Backtracking) If N is the root, return NO. Otherwise let N_f be the parent node of N with the left-most subgoal A_f.

   - Case B1: A_f is $memo_look(.)$. Goto 3 with $N = N_f$.
   - Case B2: A_f is a non-tabled subgoal. Goto 2 with N_f as the latest registered node.
   - Case B3: $A_f = q(\vec{Z})$ is a tabled subgoal. Let N be generated from N_f by resolving A_f with a clause C_{q_j}. If $N_f \rightarrow node_SUSP = 0$ then set $TB(A_f) \rightarrow clause_status[j] = 0$; else set $N_f \rightarrow node_SUSP = 0$. Goto 2 with N_f as the latest registered node.

Obviously, Algorithm 2 reduces to Algorithm 1 when P contains no tabled predicates. We now explain Algorithm 2 briefly. First we set up the root N_0 via registration (see Definition 3.2). The global variable NEW is initialized to 0, meaning that up to now no new answer has been derived for any subgoal. Then by the Depth-first policy we select the latest registered node, say N_i labeled with the goal G_i, for expansion (point 2). If the left-most subgoal A_1 of G_i is $return(\vec{I})$ (Case 1), which means the top goal G_0 has been proved true with the answer substitution $\vec{Y}/\vec{I}$, we reach a success leaf N_{i+1} labeled with $\Box$. We then do backtracking (point 3) to derive alternative answers to G_0.

If A_1 is $memo_look(N_h, p(\vec{X}), \vec{I}, \theta_h)$ (Case 2), which means that the left-most subgoal $p(\vec{X})$ at node N_h is proved true with the answer substitution $\vec{X}/\vec{I}$, we memorize $\vec{I}$ in the table $TB(p(\vec{X}))$ and set $NEW = 1$ if the answer is new. Meanwhile, if the answer $p(\vec{I})$ is a variant of the subgoal $p(\vec{X})$, we set the flag $TB(p(\vec{X})) \rightarrow COMP = 1$, indicating that the answers of $p(\vec{X})$ have been completed. After memorization, we fetch the next answer from the table and then prove the resolvent G_{i+1} of G_i and the new answer.

Case 3 is straightforward, so we move to Case 4. By the Table-first policy, we first look up answers for A_1 from the table $TB(p(\vec{X}))$. When available, we fetch the next unused answer for A_1 and create the resolvent G_{i+1}. Otherwise, we check the flag $TB(p(\vec{X})) \rightarrow COMP$ to see if the answers of $p(\vec{X})$ have been completed. If yes, which means that the subgoal A_1 at N_i has used all its answers, we backtrack to its parent node. Otherwise, we continue to derive new answers by resolving A_1 with the remaining clauses. Based on whether A_1 has any ancestor variant subgoal, we distinguish three cases (Cases 4.1, 4.2 and 4.3).

At the time that N_i is registered (see Definition 3.2), we do not know if A_1 at N_i has any ancestor variant subgoal (i.e. $N_i \rightarrow node_ANC = -1$ initially). So we check it via the ancestor list AL_{A_1} (see Definition 3.7) and update the flag $N_i \rightarrow node_ANC$ accordingly. If N_h is the closest ancestor node of N_i such that $L(N_h, N_i)$ is a loop, the other flags of N_i, namely $node_LOOP$, $node_ITER$ and $node_SUSP$, will also be updated by the procedure $nodetype_update(.)$ (see Case 4.1).

For Case 4.2, A_1 has no ancestor variant subgoal, which implies that the derivation does not get into a loop at N_i. So we seek the next clause whose head is unifiable with A_1 and whose status is *"still available,"* and use it to build the resolvent G_{i+1}. Now consider the case that no such a clause exists, which means that the subgoal A_1 at N_i has used all its answers and clauses available. In Prolog, we would fail the subgoal immediately and backtrack to its parent node. In TP-resolution, however, we cannot do this unless N_i is a non-iteration node. Suppose N_i is an iteration node (i.e. $N_i \rightarrow node_ITER = 1$). Before failing A_1 via backtracking, we do answer iteration to complete its answers. The process is quite simple. We start an iteration simply by initializing NEW to 0 and resetting the pointer $N_i \rightarrow clause_ptr$ to pointing to the first clause C_{p_j} whose status remains to *"still available"* (Case 4.2.2). Since the status of all clauses involved in loops are kept to *"still available"* during backtracking, all the loops can be regenerated by the iteration. By the end of an iteration, i.e. when we come back to N_i again and try to fail A_1 via backtracking, we check the flag NEW to see if the termination condition is satisfied. If $NEW = 0$, meaning that a fixpoint has been reached so that the answers of A_1 have been completed, we stop answer iteration by failing A_1 via backtracking (see Cases 4.2.1). Otherwise, we start a new iteration to seek more answers (Case 4.2.2).

For Case 4.3, A_1 has an ancestor variant subgoal, so the derivation has gone into a loop, say $L(N_h, N_i)$. In order to break the loop, we skip the clause C_{p_j} that is being used by the top loop node N_h. The skip of clauses may lead to loss of answers, which is the only reason why answer iteration is required. (**Remark:** Algorithm 2 uses loop checking to cut loops and adopts answer iteration to iteratively regenerate loops that are pruned by loop checking. Such a complementary use of loop checking and answer iteration is an effective way of cutting infinite loops while guaranteeing the completeness of answers.)

Backtracking (point 3) is done as usual except that the status of the clauses that have been used should be set to *"no longer available"* (Case B3). Let C_{q_j} be the clause that is being used by

N_f. If no loop occurred that went through N_f via C_{q_j}, the flag $N_f \rightarrow node_SUSP$ must remain to 0. In this case, we set the status of C_{q_j} in $TB(A_f)$ to *"no longer available"* because all answers of A_f by the application of C_{q_j} have been exhausted. Otherwise, when a loop occurred before that went through N_f via C_{q_j}, $N_f \rightarrow node_SUSP$ must be 1 (see the procedure *nodetype_update*(.)). So we keep the status of C_{q_j} to *"still available"* while setting $N_f \rightarrow node_SUSP$ to 0 again.

Based on TP-trees, we have the following standard definitions.

Definition 3.10 Let TP_{G_0} be a TP-tree of $P \cup \{G_0\}$. All leaves of TP_{G_0} labeled by $\Box$ are *success* leaves and all other leaves are *failure* leaves. A *TP-derivation*, denoted by $G_0 \Rightarrow_{C_1,\theta_1} G_1 \Rightarrow ... \Rightarrow_{C_i,\theta_i} G_i \Rightarrow ... \Rightarrow_{C_n,\theta_n} G_n$, is a partial branch in TP_{G_0} starting at the root, where each G_i is a goal labeling a node N_i and for each $0 \leq i < n$, G_{i+1} is the resolvent of G_i and C_{i+1} with the mgu θ_{i+1}, where C_{i+1} may be a program clause or a tabled fact or blank (when the left-most subgoal of G_i is a procedure). A TP-derivation is *successful* if it ends with a success leaf and *failed*, otherwise. The process of constructing TP-derivations is called *TP-resolution*.

Example 3.3 Consider the example program P_1 again (see Section 2). Based on the dependency graph of P_1, we choose *reach* as a tabled predicate and *edge* as a non-tabled one. Now consider applying Algorithm 2 to the top goal $G_0 = \leftarrow reach(a, X)$.

We first set up the root N_0 labeled with $\leftarrow reach(a, X), return((X))$ and set $NEW = 0$ (point 1). Then we expand N_0 using the clause C_{r_1} (point 2, Cases 4, 4.1 and 4.2), which creates a table

$$TB(reach(a, X)) : (reach(a, X), \{\}, (1, 1, 1), 0)$$

and a child node N_1 (see Figure 6). Obviously there is a loop $L(N_0, N_1)$, so we call the procedure *notetype_update*$(L(N_0, N_1))$, which marks N_0 as a candidate iteration node, sets $N_0 \rightarrow clause_SUSP = 1$ and $N_1 \rightarrow node_ANC = 1$. Then by Case 4.3 the clause C_{r_2} (instead of C_{r_1}) is applied to $reach(a, Z)$ at N_1, which gives a node N_2. Next, by Case 2 the answer $reach(a, a)$ is memorized in the table (so $NEW = 1$), yielding

$$TB(reach(a, X)) : (reach(a, X), \{(a)\}, (1, 1, 1), 0)$$

and the node N_3 is derived using the first tabled fact. By successively performing Cases 3, 2 and 1, we reach a success leaf N_6 with the first answer $X = a$ to the top goal. After these steps, the table looks like

$$TB(reach(a, X)) : (reach(a, X), \{(a), (b)\}, (1, 1, 1), 0).$$

Now we do backtracking. By Cases B1 and B2 we go back until N_3. Since C_{e_2} is not unifiable with the subgoal $edge(a, X)$, we go back to N_2 and then to N_1. From N_1 we consecutively derive a failure leaf N_7 (Figure 7), a success leaf N_{12} (Figure 8) and another failure leaf N_{13} (Figure 9). After these steps, the table becomes

$$TB(reach(a, X)) : (reach(a, X), \{(a), (b), (d), (e)\}, (1, 0, 0), 0).$$

Now $reach(a, Z)$ at N_1 has used all answers in the table and has no more clause available. So we return to the root N_0. Note that since the flag $N_0 \rightarrow clause_SUSP = 1$, which shows the clause C_{r_1} that is being used by N_0 is involved in a loop, the status of C_{r_1} in $TB(reach(a, X))$ remains to *"still available"* when backtracking from N_1 to N_0 (see Case B3).

From Figures 6−9, we see that N_0 has used only the first two answers in $TB(reach(a, X))$, namely $reach(a, a)$ and $reach(a, b)$. So it continues to use the other two. By repeating Case 4, Case 1 and point 3 twice, we get another two successful derivations as depicted in Figures 10 and 11.

Now $reach(a, X)$ at N_0 has used all tabled facts in $TB(reach(a, X))$ and has no more clause available (note that C_{r_2} and C_{r_3} have already been used by N_1). Before failing it via backtracking, we check if N_0 is an iteration node (i.e. we see if $N_0 \rightarrow node_ITER$ remains to the value 1). Since N_0 is an iteration node and the flag $NEW = 1$, by Case 4.2.2 we do answer iteration. It is easy to check that no new answer will be derived (see Figure 4), so by the end of the first iteration NEW remains to the value 0. Thus by Case 4.2.1, the flag $COMP$ of $TB(reach(a, X))$ is changed to 1, showing that the answers of $reach(a, X)$ have been completed.

Finally, by point 3 the answer NO is returned, which terminates the algorithm. Therefore by putting together Figures 6−11 and the figures for answer iteration (which are omitted here) we obtain the TP-tree TP_{G_0} of $P_1 \cup \{G_0\}$.

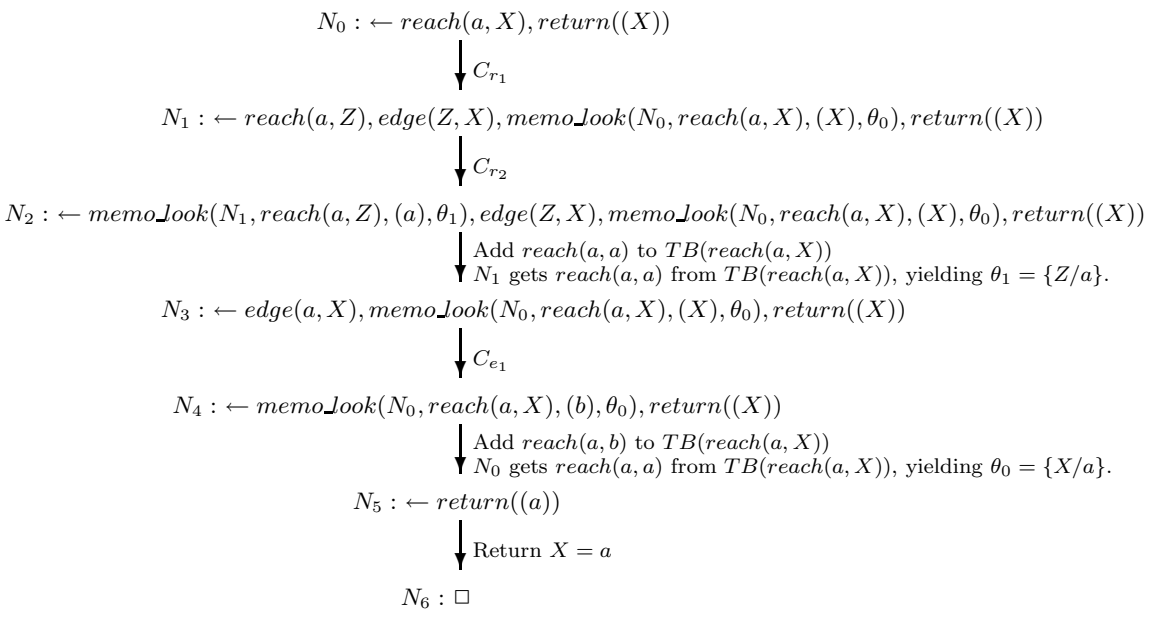

Figure 6: The first successful TP-derivation with an answer $X = a$.

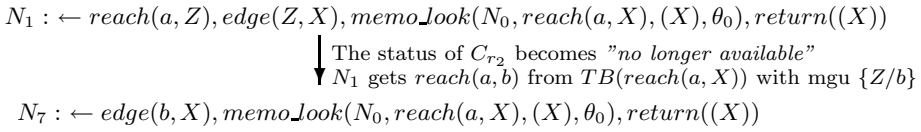

Figure 7: A failed TP-derivation.

The following example is also useful in illustrating TP-resolution.[7] To simplify the presentation, in the sequel, in depicting derivations we omit subgoals like $memo_look(.)$ and $return(.)$ unless they are required to be explicitly present.

Example 3.4 Consider the logic program

P_2: $p(a,b,c).$ C_{p_1}
$p(X,Y,Z) \leftarrow p(Z,X,Y).$ C_{p_2}

Choose p as a tabled predicate. Let $G_0 = \leftarrow p(X,Y,Z)$ be the top goal. The TP-tree of $P_2 \cup \{G_0\}$ consists of Figures 12 and 13, which yields three answers, $p(a,b,c)$, $p(b,c,a)$ and $p(c,a,b)$.

Note that in the above examples, no new answers are derived during answer iteration (i.e. Algorithm 2 stops by the end of the first iteration). We now give another example, which shows that answer iteration is indispensable.

Example 3.5 Consider the following logic program

P_3: $p(X,Y) \leftarrow q(X,Y).$ C_{p_1}
$q(X,Y) \leftarrow p(X,Z), t(Z,Y).$ C_{q_1}
$q(a,b).$ C_{q_2}
$t(b,c).$ C_{t_1}

Choose p and q as tabled predicates and apply Algorithm 2 to the top goal $G_0 = \leftarrow p(X,Y)$. After applying the clauses C_{p_1} and C_{q_1}, we generate the derivation shown in Figure 14. We see that a loop $L(N_0, N2)$ occurs. So we do not use C_{p_1} to expand N_2 because that would repeat the loop. Instead, we try alternative clauses. Since there is no other clause in P_3 that is unifiable with $p(X,Z)$, we fail N_2 and backtrack to its parent node N_1, which leads to the derivation of Figure 15. Now, since there is no more clause available for $q(X,Y)$, we fail N_1 and go back to N_0. Note that the flag NEW has been set to 1 because new answers, $q(a,b)$ and $p(a,b)$, have been derived. Moreover, C_{q_2} is *no longer available* to $q(X,Y)$, whereas both C_{p_1} and C_{q_1} are *still available* because they are involved in a loop.

[7] This program is suggested by an anonymous referee.

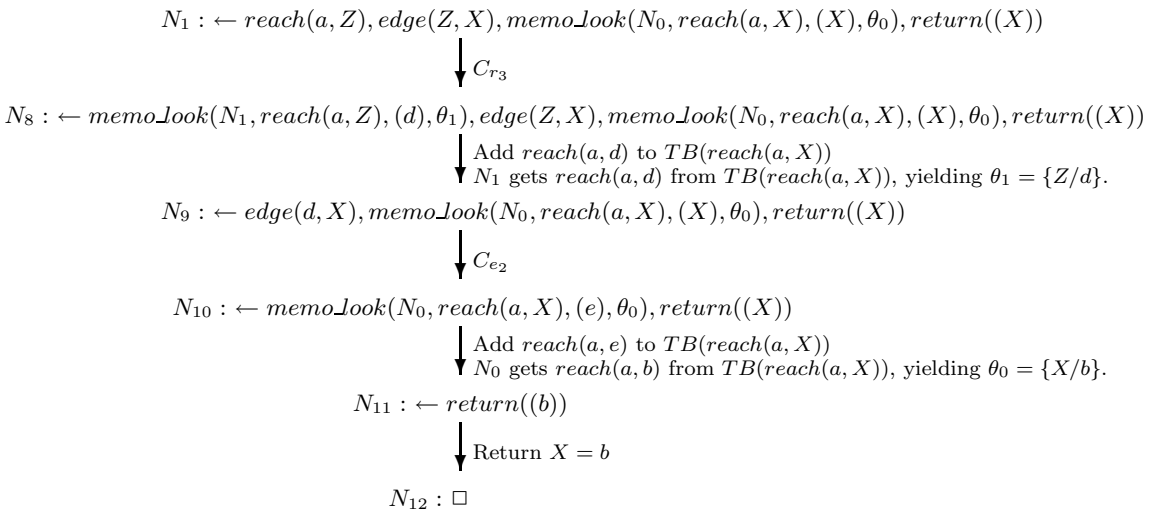

Figure 8: The second successful TP-derivation with the second answer $X = b$.

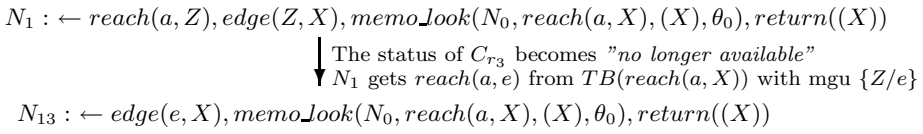

Figure 9: Another failed TP-derivation.

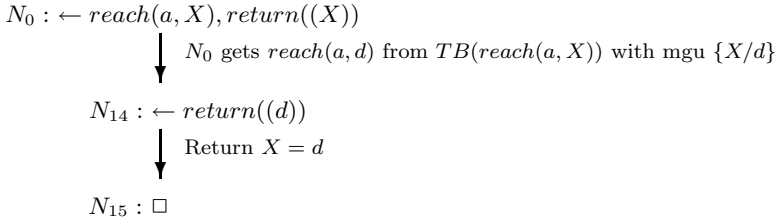

Figure 10: The third successful TP-derivation with the third answer $X = d$.

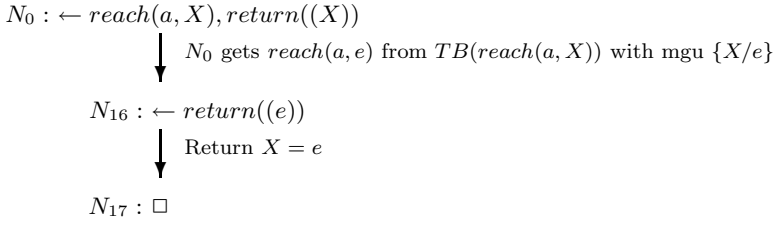

Figure 11: The fourth successful TP-derivation with the fourth answer $X = e$.

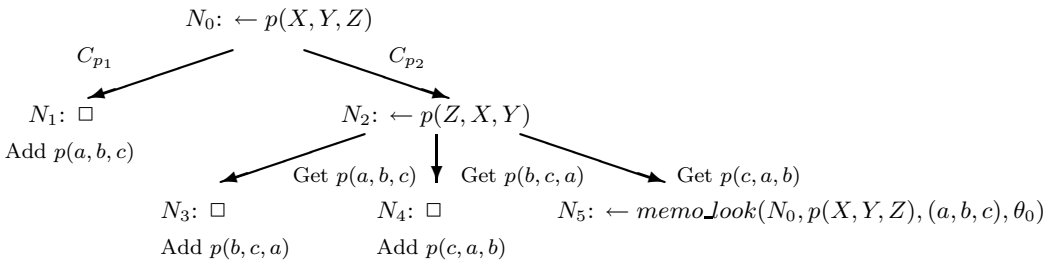

Figure 12: TP-derivations of $P_2 \cup \{G_0\}$.

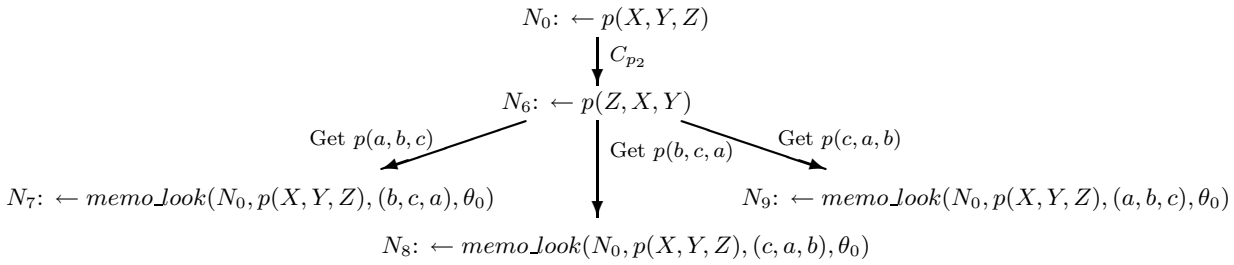

Figure 13: Answer iteration for $P_2 \cup \{G_0\}$.

At N_0 answer iteration is performed. The first iteration is shown in Figure 16, where two new answers, $q(a,c)$ and $p(a,c)$, are derived. The second iteration will derive no new answers, so the algorithm stops with the flag $COMP$ of $TB(p(X,Y))$ set to 1.

4 Characteristics of TP-Resolution

In this section, we prove the termination of Algorithm 2 and the soundness and completeness of TP-resolution. We also discuss the way to deal with the cut operator in TP-resolution.

4.1 Soundness and Completeness

In order to guarantee termination of Algorithm 2, we restrict ourselves to logic programs with the bounded-term-size property. The following definition is adapted from [19].

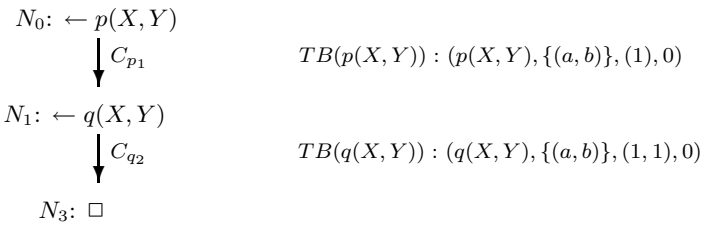

Figure 15: A successful TP-derivation.

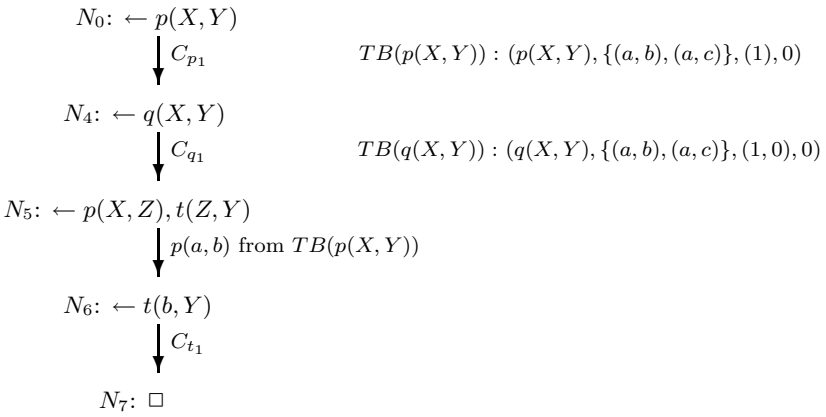

Figure 16: New answers derived via answer iteration.

Definition 4.1 A logic program P has the *bounded-term-size* property if there is a function $f(n)$ such that whenever a top goal G_0 has no argument whose term size exceeds n, then no subgoal in the TP-tree TP_{G_0} and no answer tuple in any table have an argument whose term size exceeds $f(n)$.

Obviously, all function-free logic programs have the bounded-term-size property.

Theorem 4.1 (Termination) *Let P be a logic program with the bounded-term-size property and G_0 a top goal. Algorithm 2 terminates with a finite TP-tree TP_{G_0}.*

The following lemma is required to prove this theorem.

Lemma 4.2 *Let G_i and G_k be two goals in a TP-derivation of $P \cup \{G_0\}$ and A_i and A_k be the left-most subgoals of G_i and G_k, respectively. If A_i is an ancestor variant subgoal of A_k then A_i is a tabled subgoal.*

Proof. Let $A_i = p(.)$. By Definitions 3.7 and 3.8, A_i being an ancestor variant subgoal of A_k implies that there is a cycle of the form $p \rightarrow ... \rightarrow p$ in the dependency graph G_P. So p is a tabled predicate and thus A_i is a tabled subgoal. $\square$

Proof of Theorem 4.1. Assume, on the contrary, that Algorithm 2 does not terminate. Then it

generates an infinite TP-tree. This can occur only in two cases: (1) it memorizes infinitely many (new) answers in tables, so we do backtracking at some nodes infinite times; and (2) it traps into an infinite derivation. We first show that the first case is not possible. Since P has the bounded-term-size property, all tabled facts have finite term size. Then, in view of the fact that any logic program has only a finite number of predicate, function and constant symbols, all tabled facts having finite term size implies that any table has only a finite number of tabled facts.

We now assume the second case. Since P has the bounded-term-size property and contains only a finite number of clauses, any infinite derivation must contain an infinite loop, i.e. an infinite set of subgoals, $A_0, A_1, ..., A_k, ...$, such that for any $i \geq 0$, A_i is both an ancestor subgoal and a variant of A_{i+1}. This means that all the A_is are tabled subgoals (Lemma 4.2). However, from Cases 4 and 4.3 of Algorithm 2 we see that such a set of subgoals will never be generated unless P contains an infinite set of clauses whose heads are unifiable with the A_is, a contradiction. □

To simplify the proof of soundness and completeness, we assume, in the sequel, that all predicates are tabled predicates.

Theorem 4.3 (Soundness and Completeness) *Let P be a logic program with the bounded-term-size property and $G_0 = \leftarrow A_1, ..., A_m$ a top goal with the list $\vec{Y}$ of variables. Let TP_{G_0} be the TP-tree of $P \cup \{G_0\}$ and ST_{G_0} the SLD-tree of $P \cup \{G_0\}$ via the left-most computation rule. Then TP_{G_0} and ST_{G_0} have the same set of answers to G_0.*

Proof. (Soundness) By the PMF mode, each tabled fact is an intermediate answer of some subgoal (called *sub-refutation* in [17]) in an SLD-derivation in ST_{G_0}. Since the answer $\vec{I}$ returned at any success leaf in TP_{G_0} is an instance of $\vec{Y}$ such that each $A_i\vec{Y}/\vec{I}$ is an instance of a tabled fact, $\vec{Y}/\vec{I}$ must be the answer substitution of some successful SLD-derivation in ST_{G_0}.

(Completeness) Algorithm 2 works in the same way as Algorithm 1 (i.e. it expands and backtracks on nodes in the same way as Algorithm 1) except (1) it is based on the PMF mode, (2) after finishing backtracking for answers of a subgoal $A_f = q(.)$ through the application of a clause C_{q_j}, the status of C_{q_j} w.r.t. A_f will be set to *"no longer available"* (see Case B3), and (3) loops are handled by skipping repeated clauses and doing answer iteration. Since the PMF mode preserves the answers of SLD-resolution and point (2) is only for the purpose of avoiding redundant computations (i.e. when variant subgoals of A_f later occur, they will directly use the tabled answers instead of recomputing them by applying C_{q_j}), it suffices to prove that point (3) does not lose any answers to G_0.

Let SD be an arbitrary successful SLD-derivation in ST_{G_0} with loops as shown in Figure 17, where $m > 0$, N_{l_0} is an iteration node and for any $0 \leq i < m$ $p(\vec{X}_i)$ is an ancestor variant subgoal of $p(\vec{X}_{i+1})$. Note that the SLD-derivation starts looping at N_{l_1} by applying C_{p_j} to $p(\vec{X}_1)$. However, Algorithm 2 will handle such loops by skipping C_{p_j} at N_{l_1} and doing answer iteration at N_{l_0}. Before showing that no answers to $p(\vec{X}_0)$ will be lost using the skipping-iterating technique, we further

explain the structure of the loops in SD as follows.

(1) For $0 \leq i < m$ from N_{l_i} to $N_{l_{i+1}}$ the proof of $p(\vec{X}_i)$ reduces to the proof of $(p(\vec{X}_{i+1}), B_{i+1})$ with a substitution θ_i for $p(\vec{X}_i)$, where each B_k $(0 \leq k \leq m)$ is a set of subgoals.

(2) The sub-refutation between N_{l_m} and N_{x_m} contains no loops and yields an answer $p(\vec{X}_m)\gamma_m$ to $p(\vec{X}_m)$. The answer substitution γ_m for $p(\vec{X}_m)$ is then applied to the remaining subgoals of N_{l_m} (see node N_{x_m}), which leads to an answer $p(\vec{X}_{m-1})\gamma_m\gamma_{m-1}\theta_{m-1}$ to $p(\vec{X}_{m-1})$. Such process continues recursively until an answer $p(\vec{X}_0)\gamma_m...\gamma_0\theta_{m-1}...\theta_0$ to $p(\vec{X}_0)$ is produced at N_{x_0}.

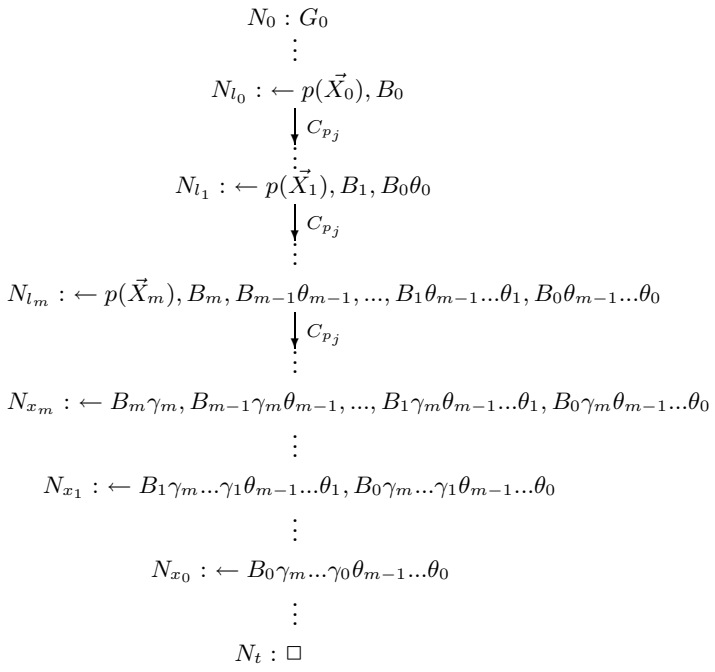

Figure 17: An SLD-derivation with loops.

We now prove that a variant of the answer $p(\vec{X}_0)\gamma_m...\gamma_0\theta_{m-1}...\theta_0$ to $p(\vec{X}_0)$ will be produced by Algorithm 2 by means of answer iteration.

Since $p(\vec{X}_0)$ and $p(\vec{X}_m)$ are variants, via backtracking from N_{l_1} up to N_{l_0} a variant of the sub-refutation between N_{l_m} and N_{x_m} can be generated, which starts from N_{l_0} via C_{p_j}. This means that a variant of the answer $p(\vec{X}_m)\gamma_m$ to $p(\vec{X}_m)$ can be derived via backtracking from N_{l_1} up to N_{l_0}, independently of the sub-derivation below N_{l_1}.

Let us do backtracking from N_{l_1} up to N_{l_0} and store all intermediate answers in their tables. So $p(\vec{X}_m)\gamma_m$ is in $TB(p(\vec{X}_0))$. Now we regenerate the loop $L(N_{l_0}, N_{l_1})$ (the first iteration).

Since $p(\vec{X}_0)$ and $p(\vec{X}_{m-1})$ are variants, a variant of the sub-refutation between $N_{l_{m-1}}$ and $N_{x_{m-1}}$, where the sub-refutation between N_{l_m} and N_{x_m} is replaced by directly using the answer $p(\vec{X}_m)\gamma_m$, can be generated via backtracking from N_{l_1} up to N_{l_0}. That is, a variant of the answer

$p(\vec{X}_{m-1})\gamma_m\gamma_{m-1}\theta_{m-1}$ to $p(\vec{X}_{m-1})$ can also be derived via backtracking from N_{l_1} up to N_{l_0} when the tabled answer $p(\vec{X}_m)\gamma_m$ is used. So we do the backtracking, store $p(\vec{X}_{m-1})\gamma_m\gamma_{m-1}\theta_{m-1}$ in $TB(p(\vec{X}_0))$, and then regenerate the loop $L(N_{l_0}, N_{l_1})$ (the second iteration).

Continue the above process recursively. After (at most) m iterations, a variant of the answer $p(\vec{X}_0)\gamma_m...\gamma_0\theta_{m-1}...\theta_0$ to $p(\vec{X}_0)$ will be derived and stored in $TB(p(\vec{X}_0))$.

The above arguments show that although the branch below N_{l_1} via C_{p_j} is skipped by Algorithm 2, by means of answer iteration along with tabling no answers will be lost to $p(\vec{X}_0)$. Therefore, when a fixpoint is reached at N_{l_0}, which means no new answers to $p(\vec{X}_0)$ can be derived via iterations, all answers of $p(\vec{X}_0)$ must be exhausted and stored in $TB(p(\vec{X}_0))$ (in such a case, the flag $TB(p(\vec{X}_0)) \rightarrow COMP$ is set to 1). We now prove that the fixpoint can be reached in finite time even if $m \rightarrow \infty$.

Let $m \rightarrow \infty$. Then SD contains infinite loops. Since P has the bounded-term-size property and only a finite number of clauses, we have only a finite number of subgoals and any subgoal has only a finite number of answers (up to variable renaming). Let N be the number of all answers of all subgoals. Since before the fixpoint is reached, in each iteration at N_{l_0} at least one new answer to some subgoal will be derived, the fixpoint will be reached after at most N iterations.

To sum up, Algorithm 2 traverses ST_{G_0} as follows: For any SLD-derivation SD in ST_{G_0}, if it has no loops Algorithm 2 will generate it based on the PMF mode while removing redundant application of clauses; otherwise, Algorithm 2 will derive the answers of subgoals involved in the loops by means of answer iteration. In either case, Algorithm 2 terminates and preserves the answers of SLD-resolution. As a result, if SD is successful with an answer to G_0, there must be a successful TP-derivation in TP_{G_0} with the same answer (up to variable renaming). □

4.2 Dealing with Cuts

The cut operator, !, is very popular in Prolog programming. It basically serves two purposes. One is to simulate the *if-then-else* statement, which is one of the key flow control statements in procedural languages. For example, in order to realize the statement *if-A-then-B-else-C*, we define the following:

$H \leftarrow A, !, B.$
$H \leftarrow C.$

The other, perhaps more important, purpose of using cuts is to prune the search space by aborting further exploration of some remaining branches, which may lead to significant computational savings. For instance, the following clauses

$p(\vec{X}) \leftarrow A_1, ..., A_m, !.$
$C_{p(.)}$*: the remaining clauses defining* $p(.)$.

achieve the effect that for any $\vec{X}$ whenever $A_1, ..., A_m$ is true with an mgu θ, we return $p(\vec{X})\theta$ and stop searching the remaining space (via backtracking on the A_is and using the remaining clauses $C_{p(.)}$) for any additional answers of $p(\vec{X})$.

The cut operator requires a strictly sequential strategy − Prolog-strategy for the selection of goals, subgoals and program clauses. TP-strategy is an enhancement of Prolog-strategy with the following two policies for dealing with tabled facts (see Definition 3.6): Table-first when both tabled facts and program clauses are available and Top-down for the selection of tabled facts. Since new answers are always appended to the end of tables, by the PMF mode, such an enhancement does not affect the original sequentiality of Prolog-strategy. That is, TP-strategy supports the cut operator as well.

Before enhancing Algorithm 2 with mechanisms for handling cuts, we recall the operational semantics of cuts.

Definition 4.2 Let P be a logic program that contains the following clauses with a head $p(.)$:

$$\begin{array}{ll} p(.) \leftarrow .... & C_{p_1} \\ \quad \vdots & \\ p(\vec{Y}) \leftarrow B_1, ..., B_m, !, B_{m+2}, ..., B_{m+k} & C_{p_i} \\ \quad \vdots & \\ p(.) \leftarrow .... & C_{p_n} \end{array}$$

Let $p(\vec{X})$ be a subgoal such that $p(\vec{X})\theta = p(\vec{Y})\theta$. The semantics of ! in C_{p_i} is defined as follows: During top-down evaluation of $p(\vec{X})$, by the left-most computation rule whenever $(B_1, ..., B_m)\theta$ succeeds with an mgu θ_1, all the remaining answers to the subgoal $p(\vec{X})$ are obtained by computing $(B_{m+2}, ..., B_{m+k})\theta\theta_1$, with the backtracking on the B_js $(1 \leq j \leq m)$ and the remaining clauses C_{p_j}s $(i < j \leq n)$ ignored. In other words, we force two *skips* when backtracking on the cut: the skip of all B_js $(1 \leq j \leq m)$ and the skip of all C_{p_j}s $(i < j \leq n)$.

It is quite easy to realize cuts in TP-resolution. Let N_h be a node labeled by a goal

$G_h = \leftarrow p(\vec{X}), ...$

and the clauses for $p(.)$ be as in Definition 4.2. Let

$G_{h+1} = \leftarrow (B_1, ..., B_m)\theta, !, (B_{m+2}, ..., B_{m+k})\theta, ...$

be the resolvent of G_h and C_{p_i}. When evaluated as a subgoal for forward node expansion, ! is unconditionally true. However, during backtracking, by Definition 4.2 it will skip all B_js by directly jumping back to the node N_h. In order to formalize such a jump, we attach to the subgoal ! a node name N_h as a directive for backtracking. That is, we create a subgoal $!(N_h)$, instead of !, in the resolvent G_{h+1}.

Then cuts are realized in TP-resolution simply by adding to Algorithm 2, before Case 1 in point 2, the case

- Case 0: A_1 is $!(N_h)$. Set $G_{i+1} = \leftarrow A_2, ..., A_m$ and $N_h \rightarrow node_SUSP = 0$, and goto 2.

and, before Case B1 in point 3, the case

- Case B0: A_f is $!(N_h)$. Let $A_h = p(\vec{X})$ be the left-most subgoal at N_h and C_{p_i} be the clause that is being used by A_h. If A_h is a non-tabled subgoal then goto 3 with $N = N_h$. Otherwise, if $N_h \rightarrow node_SUSP = 0$ then set $TB(A_h) \rightarrow clause_status[j] = 0$ for all $j \geq i$; else set $N_h \rightarrow node_SUSP = 0$ and $N_h \rightarrow clause_ptr = null$. Goto 2 with N_h as the latest registered node.

For Case 0, since ! is unconditionally true, $G_{i+1} = \leftarrow A_2, ..., A_m$. For Case B0, we do backtracking on the subgoal $!(N_h)$ at node N_f. By Definition 4.2, we will skip all nodes used for evaluating $(B_1, ..., B_m)\theta$ and then skip all clauses C_{p_j}s with $j > i$. The first skip is done by jumping from N_f back to N_h. If $p(\vec{X})$ at N_h is a non-tabled subgoal, the second skip is done by failing the subgoal via backtracking. Otherwise, we consider two cases.

1. Assume $N_h \rightarrow node_SUSP = 0$. This means the evaluation of $(B_{m+2}, ..., B_{m+k})\theta\theta_1$ did not encounter any loop that goes through N_h via C_{p_i}, so that all answers of $(B_{m+2}, ..., B_{m+k})\theta\theta_1$ must have been exhausted via backtracking. Thus there will be no new answers of $p(\vec{X})$ that can be derived by applying the clauses C_{p_j}s ($j \geq i$). Therefore, in this case the second skip is achieved by changing the status of the C_{p_j}s in $TB(p(\vec{X}))$ to *"no longer available"*.

2. Assume $N_h \rightarrow node_SUSP = 1$. Since the flag $N_h \rightarrow node_SUSP$ is initialized to 0 after the evaluation of $(B_1, ..., B_m)\theta$ (see Case 0), $N_h \rightarrow node_SUSP = 1$ means that the evaluation of $(B_{m+2}, ..., B_{m+k})\theta\theta_1$ encountered loops that go through N_h via C_{p_i}. So answer iteration is required to exhaust the answers of $(B_{m+2}, ..., B_{m+k})\theta\theta_1$. Hence, in this case the second skip is done simply by clearing the pointer $N_h \rightarrow clause_ptr$, so that no more clauses will be available to $p(\vec{X})$ at N_h.

Example 4.1 Consider the following logic program:

P_4: $p(X, Y) \leftarrow p(X, Z), t(Z, Y).$ C_{p_1}
$p(X, Y) \leftarrow p(X, Y), !.$ C_{p_2}
$p(a, b).$ C_{p_3}
$p(f, g).$ C_{p_4}
$t(b, c).$ C_{t_1}

Choose p as a tabled predicate. Let $G_0 = \leftarrow p(X,Y)$ be the top goal. By applying C_{p_1} to the root N_0 we generate N_1, where the first loop $L(N_0, N_1)$ occurs (see Figure 18). Then C_{p_2} is applied, which yields the second loop $L(N_1, N_2)$. Since C_{p_2} is being used by N_1, C_{p_3} is used to expand N_2, which gives the first tabled fact $p(a,b)$. At N_3, the cut succeeds unconditionally, which leads to N_4. Then C_{t_1} is applied, giving the first success leaf N_5 with the second tabled fact $p(a,c)$ added to $TB(p(X,Y))$.

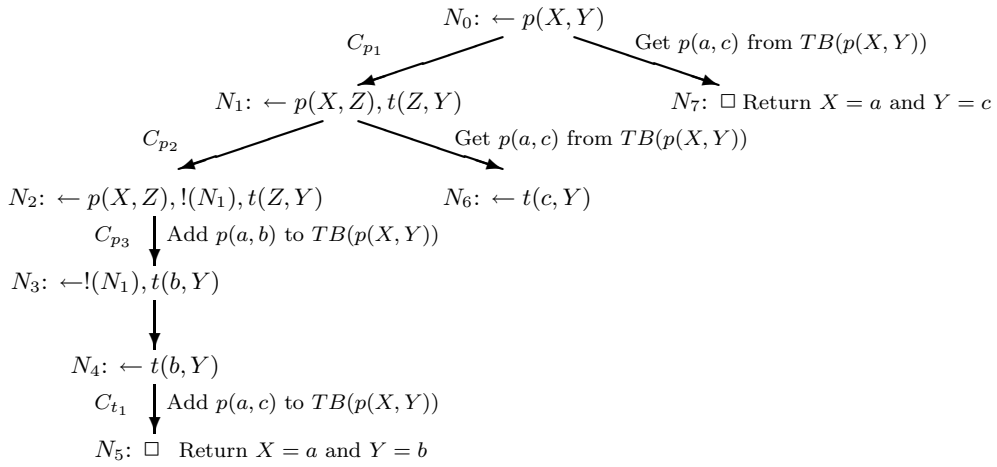

Figure 18: TP-derivations with cuts.

We backtrack to N_4 and then to N_3. Due to the subgoal $!(N_1)$, we directly backtrack to N_1 (the first skip). The status of C_{p_2}, C_{p_3} and C_{p_4} in $TB(p(X,Y))$ is then changed to *"no longer available"* (the second skip). At N_1, the second tabled fact $p(a,c)$ is used, which yields a failure leaf N_6. Next we go back to N_0, where the second tabled fact $p(a,c)$ is used, which gives the second success leaf N_7.

Similar extension can be made to Algorithm 1 to deal with cuts in Prolog. By comparison of the two, we see that without loops, cuts in TP-resolution achieve the same effect as in Prolog. When there are loops, however, TP-resolution still reaches conclusions, whereas Prolog will never stop. The following representative example illustrates such a difference.

Example 4.2 The following two clauses

$$not_p(X) \leftarrow p(X), !, fail. \qquad C_{np_1}$$
$$not_p(X). \qquad C_{np_2}$$

define the predicate *not_p* which says that for any object X, $not_p(X)$ succeeds if and only if $p(X)$ fails. Let $G_0 = \leftarrow not_p(a)$ be the top goal and the programs P_{5_i} be defined as follows.

1. $P_{5_1} = \{C_{np_1}, C_{np_2}\}$. As $p(a)$ fails, C_{np_2} is applied, so that both Prolog and Algorithm 2 give an answer YES to G_0.

2. $P_{5_2} = \{C_{np_1}, C_{np_2}, p(a)\}$. As $p(a)$ succeeds, the cut ! in C_{np_1} is executed. Since the subgoal $fail$ always fails, the backtracking on ! skips C_{np_2}, so that both Prolog and Algorithm 2 give an answer NO to G_0.

3. $P_{5_3} = \{C_{np_1}, C_{np_2}, p(X) \leftarrow p(X)\}$. Note that p is a tabled predicate. As Prolog goes into an infinite loop in proving the subgoal $p(a)$, no answer to G_0 can be obtained. However, Algorithm 2 breaks the loop by deriving a negative answer to $p(a)$, so that C_{np_2} is applied, which leads to an answer YES to G_0.

As we mentioned earlier, cuts are used for two main purposes: (1) simulate the *if-A-then-B-else-C* statement, i.e. treat B and C to be two exclusive objects; (2) prune the search space, i.e. force the two skips when backtracking on cuts (see Definition 4.2). Since the second purpose exactly corresponds to the operational semantics of cuts, it is achieved by both Prolog and TP-resolution in any situations. It turns out, however, that the first purpose cannot be achieved in arbitrary situations. The following example illustrates this.

Example 4.3 Consider the following logic program:

P_6: $p(X) \leftarrow q(X), p(b), !, B.$ C_{p_1}
$p(X) \leftarrow C.$ C_{p_2}
$q(a).$ C_{q_1}
$B.$ C_{B_1}
$C.$ C_{C_1}

It is easy to check that this program will generate no loops. However, the two clauses C_{p_1} and C_{p_2} do not represent

if $q(X)$ *and* $p(b)$ *then* B *else* C

because evaluating $p(X)$ by Prolog/TP-resolution will lead to both C and B being executed, which violates the intension that they are exclusive objects.

Definition 4.3 Let P be a program. We say that the effect of *if-A-then-B-else-C* is achieved using clauses of the form

$H \leftarrow A, !, B.$
$H \leftarrow C.$

if when evaluating H against P, either B (i.e. when A is true) or C (i.e. when A is false) but not both will be executed.

Based on this criterion, we give the following characterizations of the classes of programs for which cuts are effectively handled by Prolog/TP-resolution to achieve the effect of *if-A-then-B-else-C*.

Theorem 4.4 *Let P be a program with the bounded-term-size property. Let $A = A_1, ..., A_m$, $B = B_1, ..., B_n$ and $C = C_1, ..., C_q$. TP-resolution achieves the effect of if-A-then-B-else-C using the following clauses in P*

$H \leftarrow A, !, B.$
$H \leftarrow C.$

if and only if (1) if A is true with the first answer substitution θ then the evaluation of A for the first answer and the evaluation of $B\theta$ will not invoke C; (2) if A is false then the evaluation of A and the evaluation of C will not invoke B.

Proof. ($\Longrightarrow$) Straightforward.

($\Longleftarrow$) Since TP-resolution always terminates, the truth value ($true$ or $false$) of A can be definitely determined. So, for point (1), $B\theta$ will be executed with C excluded; and for point (2), C will be executed with B excluded. Therefore, the effect of *if-A-then-B-else-C* is achieved. □

Theorem 4.5 *The conditions of Prolog achieving the effect of if-A-then-B-else-C using the following clauses*

$H \leftarrow A, !, B.$
$H \leftarrow C.$

are the two conditions for TP-resolution plus a third one: (3) the evaluation of A for its first answer will not go into a loop.

Proof. Without loops in evaluating A for its first answer, the truth value ($true$ or $false$) of A can be definitely determined. Otherwise, neither B nor C will be executed, which violates the criterion of Definition 4.3. □

By Theorem 4.4, for programs P_{5_1}, P_{5_2} and P_{5_3} (see Example 4.2) the two clauses C_{np_1} and C_{np_2} can be used by TP-resolution to represent *if-$p(X)$-then-$fail$-else-true*. By Theorem 4.5, however, Prolog cannot achieve such effect for P_{5_3} because the evaluation of $p(X)$ will go into a loop. Moreover, neither TP-resolution nor Prolog can use C_{p_1} and C_{p_2} in P_6 (see Example 4.3) to represent *if-($q(X)$ and $p(b)$)-then-B-else-C* because the evaluation of $p(b)$ will invoke C, which violates point (1) of Theorem 4.4.

Summarizing the above discussion leads to the following conclusion.

Corollary 4.6 *Let P be a program with the bounded-term-size property. If Prolog effectively handles cuts for P w.r.t. the two intended purposes, so does TP-resolution; but the converse is not true w.r.t. the first purpose.*

Proof. The second purpose of using cuts is achieved by both Prolog and TP-resolution for any programs. For the first purpose, this corollary follows immediately from Theorems 4.4 and 4.5. □

5 Conclusions and Further Work

Existing tabulated resolutions, such as OLDT-resolution, SLG-resolution and Tabulated SLS-resolution, rely on the solution-lookup mode in formulating tabling. Because lookup nodes are not allowed to resolve tabled subgoals against program clauses, the underlying tabulated resolutions cannot be linear, so that it is impossible to implement such resolutions using a simple stack-based memory structure like that in Prolog. This may make their implementation much more complicated (SLG-WAM for XSB is a typical example [12], in contrast to WAM/ATOAM for Prolog [21, 23]). Moreover, because lookup nodes totally depend on solution nodes, without any autonomy, it may be difficult to handle some strictly sequential operators such as cuts as effectively as in Prolog ([11, 13]).

In contrast, TP-resolution presented in this paper has the following novel properties.

1. It does not distinguish between solution and lookup nodes. Any nodes can resolve tabled subgoals against program clauses as well as answers in tables provided that they abide by the Table-first policy, regardless of when and where they are generated.

2. It makes linear tabulated derivations based on TP-strategy in the same way as Prolog except that infinite loops are broken and redundant computations are reduced. The resolution algorithm (Algorithm 2) is sound and complete for positive logic programs with the bounded-term-size property and can be implemented by an extension to any existing Prolog abstract machines such as WAM [21] or ATOAM [23].

3. Due to its linearity, cuts can be easily realized. It handles cuts as effectively as Prolog in the case that cuts are used for pruning the search space, and better than Prolog in the case for simulating the *if-then-else* statement.

However, TP-resolution has some disadvantages. In particular, an efficient implementation requires further investigation of the following issues.

1. Because it is a mixture of loop checking and tabling, ancestor checking is required to see if a TP-derivation has gone into a loop. That could be costly. Therefore, fast ancestor checking algorithms remain to be explored in further investigation.

2. Answer iteration introduces redundant computations for those programs and goals where the iteration is totally redundant (see, for example, the programs P_1 and P_2 in Examples 3.3 and 3.4 where no new answers can be derived through the iteration). Methods of determining in what cases answer iteration can be ignored remain an interesting open problem.

We have recently extended TP-resolution to compute the well-founded semantics of general logic programs. A preliminary report on the extension appears in [15]. We are also working on the implementation of TP-resolution to realize a linear tabulated Prolog system.

Acknowledgements

We are grateful to the three anonymous referees for their insightful comments, which have greatly improved the presentation. The first author is supported in part by Chinese National Natural Science Foundation and Trans-Century Training Program Foundation for the Talents by the Chinese Ministry of Education.
